I. Abstract

This project utilizes the chest X-ray anomaly detection dataset released by VinBigData for the 2021 Kaggle competition, with the objective of developing a high-performing detection model for the challenging task of chest anomaly detection. This domain is particularly demanding, as even subtle abnormalities can have significant clinical consequences.

The final metrics of our ensemble approach combine YOLO and Faster R-CNN using advanced Weighted Box Fusion (WBF), significantly pushing detection performance metrics implicitly beyond single standalone frameworks. This report documents the extensive inputs, baseline tests, ensemble optimizations, and mathematical logic generated to achieve robust mapping convergence natively onto 14 abnormality classes.

II. Introduction

Computer vision algorithms have long played a significant role in the analysis of medical images, supporting clinical decision-making in use cases such as MRI or CT images. In particular, computer vision techniques applied to X-ray imaging can serve as an effective preliminary tool for the early detection and diagnosis of diseases with a visual interpretation. VinBigData leveraged the growing interest in this field by organizing a competition in 2021 and releasing a carefully curated and extensively annotated dataset of chest X-ray anomalies [1].

Building on recent advances addressing this challenging computer vision problem, our work aims to leverage and adapt effective existing baseline approaches while further developing advanced methods based on state-of-the-art detection models scaling correctly through native bounding-box ensembles.

III. Dataset and Preprocessing

A. Data Overview

This study utilizes the original VinBigData Chest X-ray dataset, which consists of high-resolution DICOM files. The dataset features a significant number of images categorized broadly into “No finding” and positive images containing varied bounding box (BBox) annotations representing 14 distinct chest abnormalities.

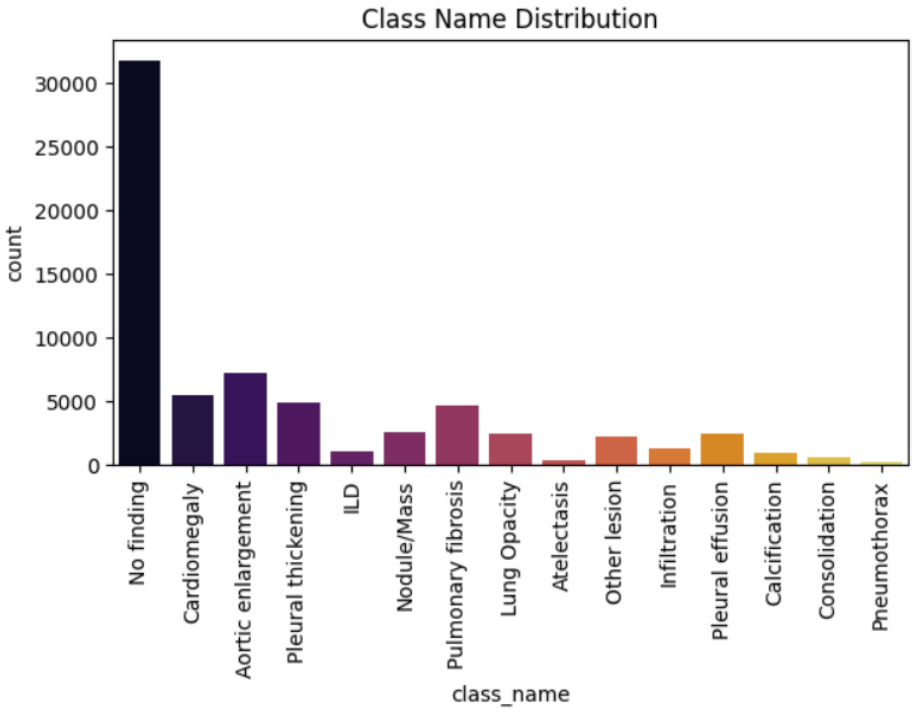

Fig. 1. Input Image Annotation Classes

The original dataset comprises 18,000 chest X-ray images, divided into 15,000 annotated training images and 3,000 test images without annotations, which were reserved for evaluation in the competition. The annotations for the training images are provided as 67,914 bounding-box coordinates (stored as x_max, y_max, x_min, y_min), stored in a tabular format where each record is associated with an image identifier and the corresponding ground-truth anomaly class label.

Overall, 10,606 images contain no detected anomalies and are labeled as the "No Finding" class, accounting for approximately 67% of the dataset.

B. File Structure and Stratified Splitting

From the original dataset, only the train folder was utilized for our comprehensive modeling pipeline. To effectively evaluate and train the detectors, we extracted and transformed these images into a clean, custom processed directory.

We split the available data into train, val, and test subsets using a rigorous stratified split. This stratification ensured that the proportion of "No finding" images to images with positive findings remained consistent across all three splits, preventing class imbalance skew during evaluation.

C. Preprocessing Pipeline

Prior to model development, we established preprocessing pipelines to convert the original medical .dicom arrays into formats directly suitable for deep learning object detectors.

a) *Baseline Image Processing (1-channel 8-bit):* For the foundational image processing branch, the pixel array representing the medical image was extracted from the .dicom

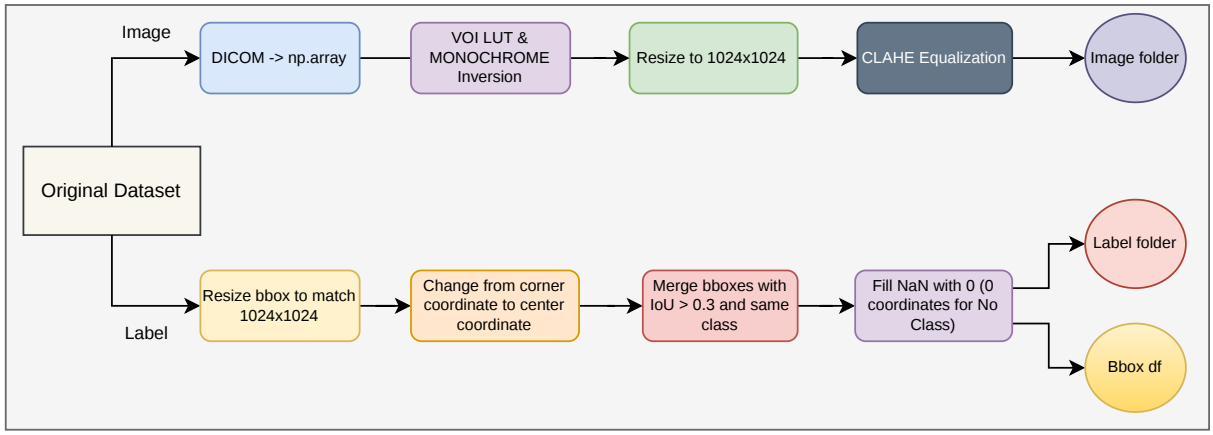

Fig. 2. Data Preparation Pipeline

files and converted into NumPy arrays using the pydicom library. We further applied the Volume of Interest Look-Up Table (VOI LUT) transformation to improve the interpretability of the 16-bit DICOM images by enhancing clinically relevant intensity ranges. Finally, pixel intensities were normalized and inverted so that anatomical structures appear bright against a dark background.

Because the original images were stored at varying resolutions, all images were resized to a uniform resolution of 1024×1024 pixels to ensure consistency during model training. In addition, contrast enhancement was applied using Contrast Limited Adaptive Histogram Equalization (CLAHE), which improves local contrast and helps emphasize clinically relevant structures within the images. This single-channel extraction served as the evaluation point for our foundational comparison tests.

b) *Advanced Image Processing (3-channel 8-bit, Localization Only):* To fully leverage standard computer vision architectures (which typically expect rich 3-channel 8-bit RGB

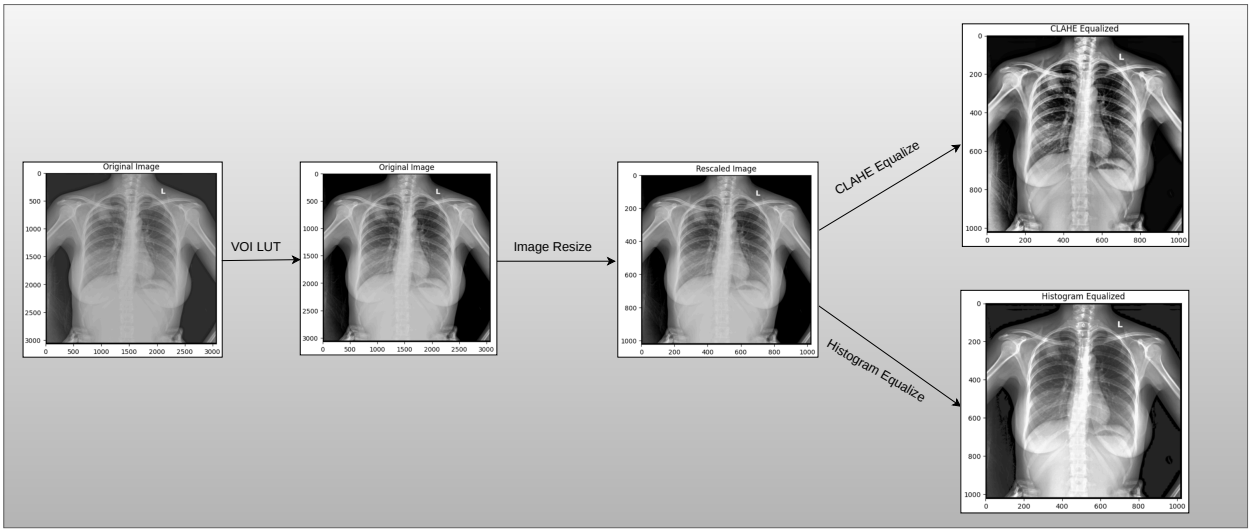

Fig. 3. Comparison between Histogram Equalization and CLAHE Extracted Processing

inputs natively), we implemented a deterministic feature extraction conversion during advanced preprocessing for the YOLO and Faster R-CNN pipelines. Crucially, this advanced 3-channel pipeline was designed and utilized **strictly for localization tasks** (i.e., binary classification of "Finding" vs. "No Finding" bounding boxes), bypassing the 14-class differentiation during this specific phase.

The arrays are stacked into a $(H \times W \times 3)$ representation utilizing multi-band transformations:

- **Channel 1 (Standard Window):** The raw pixel array is normalized utilizing percentile clipping (0.5% to 99.5%) to remove outliers, scaled to $[0, 1]$, and converted directly to standard 8-bit (uint8) space. This serves as the baseline visual representation.
- **Channel 2 (Local Contrast):** Contrast Limited Adaptive Histogram Equalization (CLAHE) is tightly computed over the 16-bit array with a clip limit of 2.0 to enhance local boundary contrast.
- **Channel 3 (Spatial Detail):** A Laplacian filter (kernel size 3) is applied to extract spatial details and edge enhancements.

This 3-channel extraction ensures that baseline windowing, local contrast mapping, and high-frequency edge details are distinctly preserved for the backbone CNNs, bypassing standard gray-to-RGB duplications.

c) *Baseline Label Processing:* For label processing, bounding-box coordinates were first rescaled to correspond to the standardized 1024×1024 image resolution. The rescaled coordinates were then converted into required structural models like normalized center mapping constraints (cx, cy, w, h) for initial training.

In addition, redundant bounding boxes were optimized by merging boxes belonging to the same class when their Intersection over Union (IoU) exceeded a threshold of 0.3. This procedure generated consolidated bounding boxes that more effectively represented each anomaly class while reducing annotation redundancy directly.

IV. Methodology

A. Detection Models

Two distinct architectures were utilized independently prior to combining their outputs via an ensemble methodology. All advanced processing models were constrained to simple structure localization tasks.

1) **YOLO (You Only Look Once):** Acted as our primary rapid, single-stage anchor-free detector framework. It maps spatial coordinates effectively with highly calibrated and inherently conservative bounding box confidences.
2) **Faster R-CNN:** Acted as our robust two-stage detector region-proposal framework. While generally powerful, it intrinsically generated predictions with highly inflated confidence boundaries natively scaling aggressively toward 0.999.

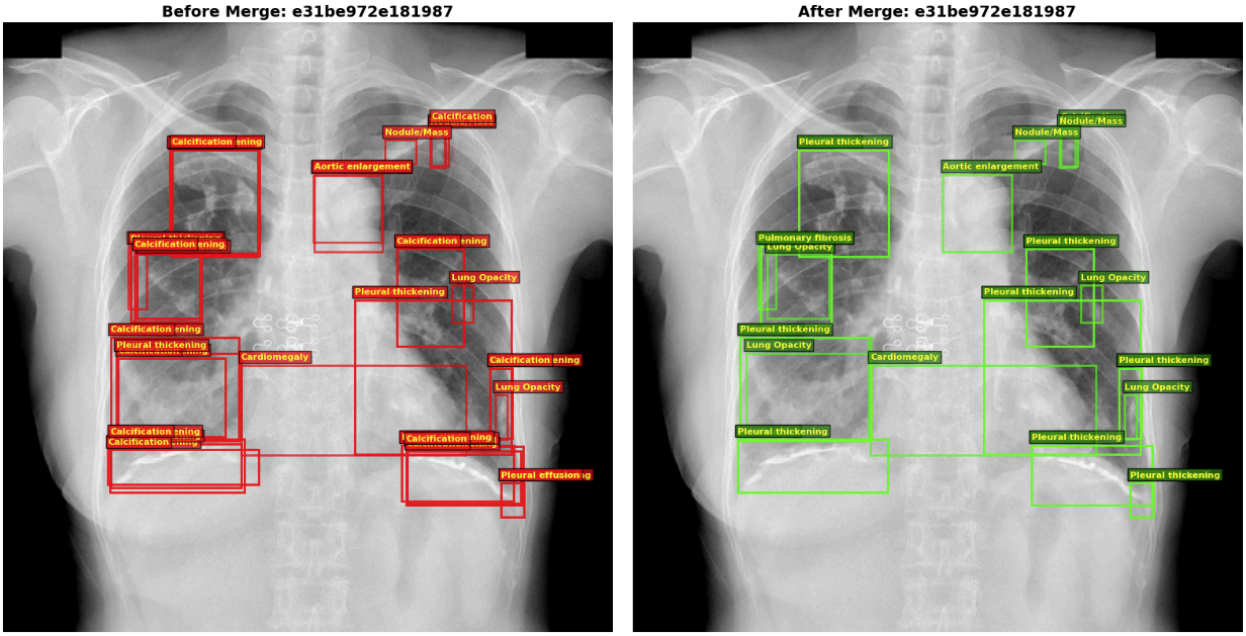

Fig. 4. Example of IoU bounding box coordinate merging

B. Ensemble Formulation (Weighted Box Fusion)

To combine predictions from YOLO and Faster R-CNN, we utilized Weighted Box Fusion (WBF). Unlike basic Non-Maximum Suppression (NMS) which simply discards overlapping bounding boxes, WBF merges them by recalculating the final bounding box coordinates. The recalculation averages the coordinates of closely overlapping predictions *weighted strictly by their respective confidence scores.*

a) *Confidence Score Discrepancy:* Unlike single-model configurations, the models output significantly different raw confidence bounds natively across validation objects:

- **Faster R-CNN Output Bounds:** $[0.050, 0.999]$
- **YOLO Output Bounds:** $[0.001, 0.847]$

Because WBF mathematically refactors fused coordinates directly using the corresponding detection confidence metric of the underlying bounding boxes, merging these two isolated confidence paradigms independently skewed spatial representation. Faster R-CNN structurally acts as a heavier mathematical vector point during convergence natively due to its artificially inflated scalar intervals.

b) *Min-Max Normalization Integration:* To completely align mapping constraints prior to applying WBF structure combinations, a deterministic Min-Max Scaling logic was encoded universally across the inference pipeline. Prior to any fusion parameter extraction, our system sequentially processes the independent subsets and maps all scores directly into normalized scalar parameters scaling specifically from $[0.0, 1.0]$:

$$S_{\text{norm}} = \frac{S - S_{\min}}{S_{\max} - S_{\min}} \tag{1}$$

Once both models were forced onto a uniform predictive structure matrix independently per image subset (utilizing a 0.0-score fallback to maintain weight ratios on negative

zero-finding subset arrays), WBF successfully converged bounding box locations globally without inherent bias weighting logic errors toward the regional proposal structure.

C. Evaluation Metrics

To robustly capture localization precision and sensitivity, our pipeline measured the following:

- **mAP@50:** Mean Average Precision computed at an Intersection-over-Union (IoU) threshold of 0.5.
- **mAP@50-95:** Mean Average Precision averaged across IoU thresholds ranging from 0.5 to 0.95 (step 0.05). This is the primary strict metric for exact bounding box alignment.
- **FROC (Free-Response Receiver Operating Characteristic):** Used natively in medical lesion detection, it measures the average sensitivity (lesion localization fraction) explicitly plotted against discrete average False Positive (FP) rates per image (e.g., $0.125, 0.25, \ldots, 8.0$ FPs/image).

V. Results and Analysis

A. Baseline Model Performances (1-channel Input)

To establish robust benchmarking metrics, preliminary multi-class models were evaluated directly utilizing the baseline 1-channel CLAHE processed image extractions and merged label formats natively. All metrics evaluate bounds across standard IoU validation.

B. Advanced Localization Model Performances (3-channel Input)

Moving to strictly binary localization bounding utilizing our advanced 3-channel arrays, we evaluated the individual model performances prior to mapping them to our unified score ensemble. After successfully applying score normalization constraints universally across all structural subsets, the Weighted Box Fusion ensemble successfully maintained peak mapping parity, effectively combining both distributions optimally.

The optimized YOLO configuration significantly outperformed both baseline single configurations, and the properly normalized Weight Box Fusion effectively aligned coordinates globally to parallel these highest peaks natively.

VI. Conclusion

By standardizing independent model confidence intervals through strict min-max normalization frameworks and ensuring dummy matrices scale effectively across iterative

TABLE I
Baseline Model Evaluation

Model	Parameter	Precision	Recall	mAP-0.5	mAP-0.75
RT-DETR	512x512, 14 classes (baseline)	0.32	0.31	0.23	0.05
ResNet50-FasterRCNN	1024x1024, only bbox	0.12	0.26	0.15	0.13
